
AUTOMATED INTERPRETABILITY METRICS DO NOT DISTINGUISH TRAINED AND RANDOM TRANSFORMERS

Anonymous authors

ABSTRACT

Sparse autoencoders (SAEs) are widely used to turn transformer activations into sparse latents whose quality is often summarized by reconstruction metrics and automatic explanation scores. We ask whether these quantitative evaluations separate SAEs trained on fully trained transformers from SAEs trained on randomized alternatives, including models whose parameters are sampled i.i.d. from Gaussian distributions. Across Pythia model sizes, layers, and multiple randomization schemes, the empirical comparison is striking: in many evaluation conditions, randomized-transformer SAEs match the trained-model SAEs on auto-interpretability AUROC and standard reconstruction-based metrics far more closely than they match the negative control. The consistency and size of these overlaps show that high aggregate SAE scores, even when numerically strong, are not sufficient evidence that learned, computationally relevant features have been recovered. We therefore frame common SAE metrics as useful but incomplete quantitative proxies, and recommend routine randomized baselines together with targeted measures that distinguish simple token-level features from more abstract learned structure.

1 INTRODUCTION

Sparse autoencoders (SAEs) have become a central quantitative tool in mechanistic interpretability: they learn sparse latents from network activations and are then judged by how well those latents reconstruct activations and support interpretable explanations (Elhage et al., 2022; Sharkey et al., 2022; Cunningham et al., 2023; Bricken et al., 2023). In the standard setup, an overcomplete autoencoder is trained to reconstruct activation vectors while enforcing sparsity (Gao et al., 2024; Templeton et al., 2024; Lieberum et al., 2024), so that individual hidden units can be treated as candidate concepts or ‘features’ learned by the network (Park et al., 2023; Wattenberg and Viégas, 2024). As a result, progress on SAE methods is increasingly reported through numerical summaries, especially auto-interpretability scores that compare generated explanations against observed activation patterns (Bills et al., 2023; Paulo et al., 2024; Karvonen et al., 2024a).

A robust interpretability metric should separate features attributable to training from structure already induced by the data distribution, architecture, or initialization. The relevant quantitative sanity check is therefore a direct comparison between trained models and strong null models, such as models with randomly initialized weights (Adebayo et al., 2020). We apply this comparison to SAEs and find that several widely used metrics show only weak separation between trained and randomized settings. Most notably, SAEs trained on transformers with random parameters can obtain auto-interpretability scores (Bills et al., 2023; Paulo et al., 2024) that are close to those obtained from the corresponding fully trained transformer.

This empirical overlap changes how the numerical evidence should be read. A high auto-interpretability score is evidence that an explanation matches an activation pattern under the scoring task, but it is not by itself evidence that the latent captures complex computation learned during language-model training. The same score can also reflect simpler statistical regularities in the text data (Dooms and Wilhelm, 2024) or architectural inductive biases that remain present before training. Indeed, randomly initialized networks may still implement a basic transformation that preserves or amplifies sparse input structure (Section 4). Under that interpretation, SAEs can be quantitatively successful while faithfully describing a much simpler computation than the one mechanistic interpretability ultimately aims to recover.

Some SAE features from trained models clearly reflect learned computation, but aggregate metrics often provide too little comparison structure to decide whether a particular high score comes from those complex features. The practical implication is that quantitative SAE evidence should be reported with trained baselines, randomized baselines, negative controls, and explicit margins between them. Such comparisons are needed to separate artifacts and architectural priors from computations genuinely learned during training.

Finally, we use toy experiments to frame two quantitative mechanisms that could make the randomized baselines competitive. At a high level, the observed metric overlap is consistent with two hypotheses: (1) the input data already exhibits superposition, and randomly initialized neural networks largely preserve this superposition; and (2) randomly initialized neural networks amplify or even introduce superposed structure to the input data (e.g., given dense input generated i.i.d. from a Gaussian). Section 4 presents toy-model evidence for the plausibility of these mechanisms, while leaving a definitive causal account of the transformer-scale results to future work.

2 RELATED WORK

Sparse dictionary learning The quantitative idea behind ‘superposition’ has a long precedent in computational neuroscience, where visual data can be modeled as many possible signals represented by sparse combinations of active elements. Olshausen and Field (1996; 1997) showed that simple-cell receptive fields in mammalian visual cortex are well explained by sparse coding: a large set of sensory signals is represented using only a small active subset of neurons at a time. Coding theory therefore provides a natural baseline for interpreting neural activations as mixtures of underlying signals (Marshall and Kirchner, 2024).

Sparse dictionary learning (SDL) makes this comparison explicit by approximating input vectors with sparse linear combinations of learned basis vectors. The learned basis is usually overcomplete, so the number of candidate directions exceeds the input dimension and sparsity determines which directions explain each example. SDL algorithms include Independent Component Analysis (ICA), which seeks a linear representation whose components are maximally statistically independent (Bell and Sejnowski, 1995; Hyvärinen and Oja, 2000). Sparse autoencoders (SAEs) instantiate the same quantitative tradeoff with a neural-network architecture (Lee et al., 2006; Ng, 2011; Makhzani and Frey, 2014). In the typical SAE evaluation setting, a single hidden layer much wider than the activation vectors is trained to minimize reconstruction error while imposing or incentivizing sparsity in hidden activations. We refer to one hidden-layer dimension as a **latent**.

Mechanistic interpretability Recent mechanistic-interpretability work often operationalizes language-model ‘features’ or concepts as low-dimensional subspaces within internal activations (Park et al., 2023; Wattenberg and Viégas, 2024; Engels et al., 2024). When such features are sparse or superposed, successful identification should support interventions: modifying or replacing activation components to express different concepts and measurably influence model behavior (Meng et al., 2022; Zhang and Nanda, 2023; Heimersheim and Nanda, 2024; Makelov, 2024; O’Brien et al., 2024).

SAEs are one of the most common feature-discovery methods because they produce both a reconstruction metric and a sparse set of candidate directions for a chosen layer, such as the transformer residual stream (Sharkey et al., 2022; Cunningham et al., 2023; Bricken et al., 2023). Architectural variants mainly change how the encoder converts activations into sparse latent coefficients, for example through different post-encoder activation functions (Makhzani and Frey, 2014; Gao et al., 2024; Rajamanoharan et al., 2024b; Lieberum et al., 2024). Other work changes the training objective (Braun et al., 2024; Farnik et al., 2025) or evaluates SAEs trained across multiple layers simultaneously (Yun et al., 2021; Lawson et al., 2024; Lindsey et al., 2024).

SAE evaluations therefore span several quantitative targets: reconstruction error, preservation of the underlying model’s performance, recovery of specific concepts (Gurnee et al., 2023; Gao et al., 2024), representation of factual knowledge (Huang et al., 2024; Chaudhary and Geiger, 2024), and downstream effects such as whether identified latents can be used to ‘unlearn’ concepts (Karvonen et al., 2024b).

Automatic neuron description Because modern SAEs often contain tens of thousands of latents, manual description is not scalable enough to serve as the primary evaluation procedure. Yun et al. (2021) inspect tokens that maximally activate a dictionary element, but most recent pipelines collect activation patterns over a text dataset and ask a large language model to generate an explanation (e.g. Bills et al., 2023; Foote et al., 2023). These automatic-description methods have become widely adopted because they turn large latent sets into comparable numerical scores (e.g. Cunningham et al., 2023; Bricken et al., 2023; Gao et al., 2024; Templeton et al., 2024; Lieberum et al., 2024).

Bills et al. (2023) score a natural-language explanation by using it to simulate a neuron’s activation pattern and then comparing simulated activations with observed activations over dataset examples. This evaluation is commonly called auto-interpretability. Paulo et al. (2024) make the comparison cheaper by replacing simulation with classification-based fidelity scores and releasing an open-source pipeline for computing them. Choi et al. (2024) further improve explanation generation with best-of- k sampling over subsets of maximally activating examples. They also fine-tune Llama-3.1-8B-Instruct on the top-scoring explanations to obtain lower-cost ‘explainer’ and ‘simulator’ models.

Polysemanticity Lecomte et al. (2024) note that individual neurons can become polysemantic incidentally. A polysemantic neuron, or basis dimension, represents multiple interpretable concepts (Elhage et al., 2022; Scherlis et al., 2023), so random individual neurons may also appear polysemantic. Our comparison instead concerns *superposition* (Elhage et al., 2022; Chan, 2024), a layer-level representational property rather than a claim about any single neuron. Under superposition, a layer can represent more sparse features than it has dense neurons because only a few concepts are active at a given token position.

Training only the embeddings Zhong and Andreas (2024) show that transformers can acquire surprising algorithmic capabilities when training is restricted to the embeddings. That result provides an important comparison point: a largely random transformer can change behavior substantially when a small parameter subset is optimized. Our evaluation condition is different in two quantitative respects: we train SAEs rather than model parameters, and in the ‘Step-0’ and ‘Re-randomized incl. embeddings’ variants we randomize *all* transformer parameters, including embeddings. The ‘Re-randomized excl. embeddings’ variant keeps pre-trained embeddings fixed, but it does not optimize those embeddings with fixed random weights; instead, the non-embedding weights are randomized while the embeddings remain frozen (Section 3).

Random transformers for board games Karvonen et al. (2024c) found a clear empirical advantage for pre-trained over random transformers when SAEs were used to extract meaningful structure from chess games. Our language setting differs in the structure of the data distribution. Language plausibly contains sparse, semantically aligned events—for example, a concept such as ‘serendipitous’ appears rarely and in related contexts. Board-game concepts need not have the same sparsity profile: a useful tactical concept such as a knight fork may not appear as a sparse token-level event in the same way.

Random one-layer transformers Bricken et al. (2023) found that auto-interpretability scores clearly separated random and trained one-layer transformers. Our model-scale comparison is consistent with separation in smaller cases: randomized variants score relatively low for smaller models such as Pythia-70m, but the trained–randomized gap narrows substantially for larger models such as Pythia-6.9b.

3 RESULTS

Our main comparison trains per-layer SAEs on residual-stream activations from Pythia language models ranging from 70M to 7B parameters (Biderman et al., 2023). For each model size and layer, we evaluate the same SAE procedure across the following underlying-transformer variants, so that the trained model, randomized baselines, and negative control are compared under matched metrics and data:

- **Trained:** The reference condition: the usual trained Pythia model.

Figure 1: Layer-wise ‘fuzzing’ ROC curves for Pythia-6.9b, with 100 latents sampled from each SAE. The trained baseline (gray) and randomized variants (colored) occupy similar AUROC ranges across layers, while the negative control (black) remains near the chance line (dotted). The trained–randomized margin is therefore small relative to the control gap, indicating that aggregate AUROC alone is insufficient evidence for learned computation. See Figure 2 for additional metrics and model sizes, and Appendix E for multiple random seeds.

- **Re-randomized incl. embeddings:** A norm-matched random baseline in which all parameters, including embeddings, are re-initialized by sampling Gaussian noise with the same mean and variance as each corresponding trained weight matrix.
- **Re-randomized excl. embeddings:** The same norm-matched randomization, except that the embedding and unembedding matrices are held fixed at their trained values.
- **Step-0:** The original Pythia step0 checkpoint, which provides the model weights at initialization before any learning (Biderman et al., 2023).
- **Control:** A negative-control condition using the trained model, but replacing input token embeddings at inference time with i.i.d. standard Gaussian noise for each token occurrence. Because a token ID has no stable embedding vector in this condition, we expect auto-interpretability to perform at chance.

In the primary experiments, every SAE is trained on 100M RedPajama tokens (Weber et al., 2024) with an activation buffer of 10M tokens, giving a matched data budget across trained and randomized comparisons (Appendix C repeats a subset with one billion tokens and obtains similar qualitative patterns). For models below 410M parameters, we train an SAE at every layer; for Pythia-1b, we evaluate every second layer; and for Pythia-6.9b, we evaluate every fourth layer.

Unless otherwise stated, all comparisons use k -sparse autoencoders, also known as TopK SAEs (Makhzani and Frey, 2014; Gao et al., 2024), with expansion factor $R = 64$ and sparsity $k = 32$. A Pythia-160m sweep over expansion factors from 16 to 128 and sparsities 16 and 32 preserves the same relative ordering across variants, indicating that the trained–randomized similarity is not a narrow hyperparameter artifact (Figure 18). The training implementation follows Belrose et al. (2025), and the evaluations follow Caden et al. (2025) and Karvonen et al. (2024a).

Auto-interpretability We quantify auto-interpretability by turning each generated feature explanation into a classification task: given text inputs, a classifier predicts whether the explained concept is present. This produces standard classification metrics, especially the area under the receiver operating characteristic curve (AUROC), which lets us compare trained and randomized variants on the same scale. Paulo et al. (2024) define two such classification tasks, ‘fuzzing’ and ‘detection’. In ‘fuzzing’, positive and negative token examples for a latent—non-zero and zero activations, respectively—are

marked with special delimiters, and a language model identifies which examples are correctly delimited given the explanation. In ‘detection’, the language model instead identifies which examples contain activating tokens for the feature. These AUROC-based scores are cheaper alternatives to the original ‘simulation’ score of Bills et al. (2023), which compares predicted and observed activations by correlation but is expensive to compute.

Except where noted, we use ‘fuzzing’ AUROC as the primary auto-interpretability metric because it has been shown to correlate with simulation scoring (Paulo et al., 2024). Appendix B reports the same comparison structure for ‘detection’ AUROC. For each SAE, defined by an underlying model, variant, and layer, we sample 100 features to compute the auto-interpretability score. Our implementation is based on Paulo et al. (2024), and we use Meta-Llama-3.1-70B-Instruct-AWQ-INT4 both to generate explanations and to make predictions; this model is larger than the 8B models used by Choi et al. (2024) and is open-source, unlike the model used by Bills et al. (2023).

The resulting AUROC curves show that trained and randomized models are much closer to one another than either is to the control (Figures 1 and 2). Thus, the trained–randomized margin in ‘fuzzing’ AUROC is often too small to support a strong distinction between the underlying transformers, even though the same metric clearly identifies the negative control.

Evaluation We next place auto-interpretability AUROC alongside standard SAE quality metrics for Pythia models from 70M through 6.9B parameters. Across these metrics, the main empirical pattern is the same as in the ROC curves: the randomly initialized and re-randomized models (Figure 2; blue, green, orange lines) generally lie closer to the trained model (gray) than to the control (black).

The reconstruction metrics make the control gap especially visible: cosine similarity between original activations and SAE reconstructions, as well as explained variance, are often much lower for the random control than for the trained and randomized variants, and the control’s reconstruction error tends to increase across layers while the other variants decrease. One possible explanation for the control’s weaker reconstruction scores is that a Gaussian is the maximum-entropy distribution for fixed mean and variance (Jaynes, 2003); in this sense, Gaussian vectors may provide less exploitable structure for an SAE. As Gaussian-distributed activations propagate through successive layers, the activations may become less Gaussian and more sparse, making them easier to reconstruct (Section 4).

A second pattern is that the re-randomized variants (blue and orange) are often closer to the trained model than the Step-0 initialization variant (green). The difference is particularly visible in L^1 norms for larger models. We speculate that this reflects parameter scale: trained weights and initialization weights may have substantially different norms, whereas our re-randomization procedure preserves each trained matrix’s mean and variance. Layer-wise parameter scale may matter for controlling activation growth through the residual stream (Liu et al., 2020). In the AUROC rows, all non-control variants also tend to increase with model size. A possible explanation is that larger SAEs support more specific features, while each latent in a smaller SAE must cover more of the input distribution, changing the difficulty of the classification task.

Figure 2 also reports the cross-entropy (CE) loss score, or loss recovered, as a function of layer. This score is the loss increase caused by replacing original activations with SAE reconstructions, normalized by the loss increase from replacing the activations with zeros (‘ablated’). For the trained variant, these CE loss scores are comparable to reported SAE results in the literature (e.g., Kissane et al., 2024; Rajamanoharan et al., 2024a; Mudide et al., 2024). The metric is not meaningful for the randomized variants, because their language-model loss is poor regardless of whether original or reconstructed activations are used; we include it to make the evaluation condition explicit rather than to compare language-model performance across random models.

Latent explanation complexity The similarity of aggregate AUROC and reconstruction metrics does not imply that the learned latents are qualitatively identical. Our prior expectation was that randomized-transformer SAEs would mostly recover simpler text-driven features, whereas trained-transformer SAEs would also recover more abstract features, especially in later layers (Templeton et al., 2024). To make this comparison more explicit, Appendix J provides randomly sampled Pythia-6.9b features and maximally activating examples for each variant, with fuller dashboards in Appendix L.

Figure 2: Matched comparison of SAE metrics across Pythia model sizes from 70M to 6.9B parameters. Rows report the same evaluation metrics for each variant and layer, making the margins between the trained model, randomized baselines, and negative control directly visible. Across model scales, the randomized variants track the trained model much more closely than the control on most metrics, despite their different initialization histories.

Figure 3: Illustrative comparison of sparse inputs, dense projections, and outputs from a randomly initialized neural network. We sample 10K points with $n_s = 3$ sparse input features from a Lomax distribution with shape $\alpha = 1$ and scale $\lambda = 1$, then project them to $n_d = 2$ dense input features using an i.i.d. standard normal matrix. Passing the dense inputs through a two-layer ReLU MLP with hidden size $4n_d$ and mapping back with the inverse projection preserves the visible sparse structure, providing a qualitative example of how random networks can maintain or sharpen superposition.

A recurring empirical pattern is that many SAE latents activate nonzero only on one token ID or on a small set of distinct token IDs in a text dataset (e.g., Lin and Bloom, 2024; Dooms and Wilhelm, 2024). This motivates a simple quantitative proxy for feature complexity: among the maximally activating examples used for auto-interpretability, how concentrated is the latent’s activation mass over token IDs? We measure this concentration with the entropy of the observed token-activation distribution; higher entropy means the activations are spread across more token IDs and are therefore less token-specific. The distribution assigns each token ID its total latent activation across the maximally activating examples used to generate explanations. We show the relationship between entropy and ‘fuzzing’ AUROC score for individual latents in Appendix H.

The final row of Figure 2 reports this token-distribution entropy for each variant. The negative control has consistently high entropy, as expected: because each occurrence of a token ID receives an independently sampled Gaussian embedding, no token has a stable vector that can support a token-specific latent (Section 3). The trained variant shows a layer-wise increase in entropy, meaning that later-layer maximally activating examples are less dominated by a single token ID. This matches the expectation that later trained layers contain more abstract features that are less tied to token embeddings. By contrast, the randomized variants tend to have lower entropy than both the trained and control variants, indicating that their high-scoring latents are often specific to one or a few token IDs.

Taken together, the entropy results identify a dimension of evidence that aggregate SAE metrics miss: feature ‘abstractness’. Token-distribution entropy is only a proxy, but it explains how randomized variants can achieve trained-like auto-interpretability scores while relying heavily on simple, token-specific features. The trained variant differs not by having uniformly higher AUROC, but by showing a layer-wise shift toward less token-specific latents that the randomized variants do not match.

4 A TOY MODEL OF SUPERPOSITION IN RANDOM NETWORKS

Section 1 proposed two mechanisms that could explain why randomized-transformer activations obtain competitive sparsity and auto-interpretability metrics: the inputs may already exhibit superposition that random networks preserve, or the networks may amplify or introduce superposed structure. This section evaluates both mechanisms with toy models whose quantitative behavior can be inspected directly. The toy results support the plausibility of both effects, although they do not determine which mechanism dominates the transformer-scale comparisons in Section 3.

4.1 MATRIX MULTIPLICATIONS PRESERVE SUPERPOSITION

We first isolate a simple quantitative fact: multiplication by a weight matrix W can preserve superposition. Consider superposed input data x generated from n_s i.i.d. sparse features z drawn from a heavy-tailed Lomax distribution, $z \sim \text{Lomax}(\alpha, \lambda)$. A projection matrix D maps the high-

Figure 4: Mean max cosine similarity (MMCS) between standard-SAE decoder directions and the ground-truth data-generating features, plotted against the L^1 penalty coefficient following Sharkey et al. (2022). The curve shows a clear intermediate regime in which the SAE nearly recovers the data-generating features when enough latents are available.

dimensional sparse vector z into a lower-dimensional dense vector x , after which small-variance Gaussian noise Σ is added, $x \sim \mathcal{N}(x; Dz, \Sigma)$. After multiplying by any matrix W , the transformed vector $x' = Wx$ remains generated by the same sparse-feature model, but with a new dense mapping and covariance: $x' \sim \mathcal{N}(z; WDz, W\Sigma W^T)$. Thus, a random linear layer need not destroy the sparse explanatory structure that an SAE could later recover.

The same qualitative pattern can persist through nonlinear random networks. Figure 3 projects $n_s = 3$ sparse features into $n_d = 2$ dense dimensions and passes them through a simple feed-forward MLP; the outputs still exhibit visible superposed structure despite the nonlinearity. The comparison also suggests possible amplification: relative to the inputs (Figures 3a and 3b), the outputs (Figures 3d and 3e) have fewer points between the visible ‘arms.’

4.2 DO RANDOM NNS PRESERVE OR AMPLIFY SUPERPOSITION?

We test preservation and amplification more systematically using the toy-data procedure of Sharkey et al. (2022): ground-truth features are sampled on a hypersphere, and correlated coefficients are generated so that only a small number of features are active in each example (Appendix I.1). We pass these inputs through an initialized two-layer MLP and train separate SAEs on the inputs and on the outputs. The quantitative control is a Gaussian input distribution with the same mean and standard deviation as the superposed toy data. All toy SAEs use a standard architecture with an L^1 sparsity penalty (Appendix I.2).

As a calibration, we reproduce the expected recovery result from Sharkey et al. (2022): SAEs can identify the ground-truth features that generated the toy data (Figure 4). We measure this with mean max cosine similarity (MMCS), computed by taking, for each data-generating feature, the maximum cosine similarity with any SAE decoder vector and then averaging over data-generating features. MMCS is available only for the MLP inputs, where the true features are known, so output analysis requires a metric that does not rely on ground-truth directions. We therefore use the tradeoff between explained variance and sparsity as a proxy for how strongly the data exhibits superposition. Varying the L^1 penalty coefficient gives Pareto frontiers of explained variance versus sparsity (Figure 5a).

The input comparison behaves as expected: at the same explained-variance level, SAEs achieve substantially greater sparsity on the superposed inputs than on the Gaussian control (Figure 5a; orange and blue-green). After the inputs pass through the random MLP, however, the margin between superposed outputs and Gaussian outputs becomes much smaller; the superposed-output frontier is only slightly sparser at matched explained variance. This pattern suggests that randomly initialized MLP outputs can become relatively sparse regardless of whether the input distribution was explicitly superposed. We consider other sparsity measures and hyperparameters in Appendix I.

4.3 DO TOKEN EMBEDDINGS EXHIBIT SUPERPOSITION?

If random networks preserve or amplify superposition, then the transformer-scale results in Section 3 may depend partly on how much superposition already exists in language inputs. We examine this by

(a) Toy datasets following Sharkey et al. (2022). (b) 300-dim. GloVe vectors (Pennington et al., 2014).

Figure 5: Pareto-frontier comparison of explained variance versus the L^1 norm divided by the square root of the L^2 norm, used here as a sparsity measure. Each panel compares a structured dataset, a Gaussian control with matched mean and variance, and the corresponding outputs after a randomly initialized two-layer MLP (Section 4.2). Each point is one L^1 penalty coefficient, so horizontal separation at matched explained variance indicates a sparsity margin between conditions.

applying the same SAE-frontier procedure from Section 4.2 to language-derived vectors. Specifically, we train SAEs on pre-trained GloVe word vectors, Pythia embedding matrices, the outputs obtained after passing these vectors through a randomly initialized two-layer MLP, and matched Gaussian controls. The setup is otherwise unchanged, except that the number of data points is fixed by the number of word embeddings or tokens and we use a single random seed.

For GloVe vectors, the gap between the structured-vector frontier and the matched Gaussian-control frontier (Figure 5b) is smaller than the corresponding gap in the explicitly superposed toy data (Figure 5a). The more important pattern for our argument is that both frontiers improve after the vectors pass through a randomly initialized two-layer MLP. This repeated improvement supports the possibility that random neural networks can ‘sparsify’ inputs, increasing apparent superposition even when the input-control margin is modest.

5 LIMITATIONS

Our experiments show that auto-interpretability metrics can assign apparently meaningful scores to SAEs trained on randomized models, even though such models are unlikely to contain the learned language-model computations that motivate mechanistic interpretability. The comparison is necessarily limited in scope: rather than testing every architecture and dataset, we focus on the Pythia family, which is widely used in mechanistic-interpretability work (e.g., Paulo and Belrose, 2025; Ghilardi et al., 2025; Mueller, 2024), and on RedPajama-V2 as representative pre-training data for language models and SAEs.

We also use the default explanation model from the EleutherAI auto-interpretability framework (Caden et al., 2025); varying the explainer or simulator could change absolute scores and may clarify which parts of the aggregate behavior come from explanation quality versus latent structure. Our claim is therefore comparative, not absolute: we do not argue that trained-transformer SAEs contain no additional information beyond randomized-transformer SAEs, but that aggregate auto-interpretability scores and standard SAE metrics can leave this additional structure numerically under-resolved.

6 CONCLUSION

We evaluated sparse autoencoders trained on both trained and randomized transformers using the same quantitative metrics, datasets, layers, and model-size comparisons. The central empirical pattern is that, in several conditions, randomized-transformer SAEs achieve aggregate auto-interpretability and reconstruction-based scores close to those of trained-transformer SAEs and far above the negative control. At the same time, token-distribution entropy and qualitative examples show that trained-model features become more complex and less token-specific in later layers, a distinction that the aggregate metrics often compress away.

These results should not be read as evidence that SAEs trained on real models fail to learn meaningful computational features. They instead identify a measurement limitation: a high aggregate auto-interpretability score is not, by itself, strong evidence that the recovered feature is complex, learned, or computationally important. The same numerical score can be supported by simpler structure in the data distribution or architecture that remains present under random weights. Token-distribution entropy is only a preliminary proxy, but it demonstrates that targeted metrics can expose trained-randomized differences that aggregate AUROC misses. Future SAE evaluations should therefore report randomized baselines, margins against negative controls, and metrics designed to quantify the computational significance and abstractness of discovered features. Without such baselines and comparison structure, it is difficult to attribute a high SAE score specifically to learning in the underlying transformer.

A BROADER IMPACT

This work evaluates a method currently used for mechanistic interpretability of LLMs and sharpens the quantitative interpretation of its evidence. By showing that SAEs can receive similar aggregate auto-interpretability scores on randomized and trained transformers, the results clarify that these scores measure explanation-task performance but do not automatically identify learned computation.

By improving how SAE quality metrics are framed and compared, we hope this work supports better evaluation practices for SAE-like methods and, ultimately, more reliable model interpretation. Because the contribution is an empirical measurement study that highlights limits of an existing method rather than increasing model capability, we expect the risk of negative social impact to be minimal.

B AUTO-INTERPRETABILITY ROC CURVES

Figures 6, 8, and 12 provide the layer-wise ‘fuzzing’ AUROC comparisons for the 70M, 160M, and 1B models, emphasizing the margins between trained, randomized, and control variants. Figures 7, 9, and 13 repeat the same comparison for ‘detection’ AUROC.

B.1 PYTHIA 70M

Figure 6: Layer-wise ‘fuzzing’ AUROC for Pythia-70m using 100 sampled SAE latents per variant. The curves show the trained–randomized margins and their layer-wise degradation relative to the control condition.

Figure 7: Layer-wise ‘detection’ AUROC for Pythia-70m using 100 sampled SAE latents per variant. The comparison highlights similar variant-level trends and the decline in performance with layer index.

B.2 PYTHIA 160M

Figure 8: Layer-wise ‘fuzzing’ AUROC for Pythia-160m using 100 sampled SAE latents per variant. Trained and randomized variants follow similar trends, with performance degrading in later layers.

Figure 9: Layer-wise ‘detection’ AUROC for Pythia-160m using 100 sampled SAE latents per variant. The trained and randomized curves remain close enough that the metric provides limited separation across variants.

B.3 PYTHIA 410M

Figure 10: Layer-wise ‘fuzzing’ AUROC for Pythia-410m using 100 sampled SAE latents per variant. Trained and randomized models have similar score ranges, so the aggregate auto-interpretability metric gives little separation while still showing layer-wise degradation.

Figure 11: Layer-wise ‘detection’ AUROC for Pythia-410m using 100 sampled SAE latents per variant. The curves make the small trained–randomized margins visible across layers.

B.4 PYTHIA-1B

Figure 12: Layer-wise ‘fuzzing’ AUROC for Pythia-1b using 100 sampled SAE latents per variant. The trained and randomized curves remain close, and unlike smaller models there is no clear overall degradation with layer index.

Figure 13: Layer-wise ‘detection’ AUROC for Pythia-1b using 100 sampled SAE latents per variant. The comparison again shows small trained–randomized margins without a clear layer-wise quality decline.

B.5 PYTHIA 6.9B

Figure 14: Layer-wise ‘detection’ AUROC for Pythia-6.9b using 100 sampled SAE latents per variant. As in the ‘fuzzing’ results, trained and randomized variants occupy similar score ranges.

C EFFECT OF INCREASED TRAINING DATA

For our primary experiments, we trained SAEs on 100M tokens (Section 3). We verified that our results were not explained by a lack of sufficient training data by repeating a subset of these experiments with SAEs trained on 1B tokens from the RedPajama dataset (Figure 15).

Figure 15: Evaluation metrics for SAEs trained with one billion tokens on Pythia-70m and Pythia-410m. Compared with the corresponding 100M-token columns in Figure 2, the trained–randomized relationships and control gaps remain qualitatively similar.

D EFFECT OF DECREASED TRAINING DATA FOR PYTHIA-1B

Figure 16: Evaluation metrics for Pythia-1b SAEs trained with 1M versus 1B tokens. The 1M-token condition has substantially lower explained variance and CE loss score, indicating under-training; auto-interpretability is only slightly lower in early layers but declines sharply with layer index, while the entropy trends remain consistent with the main comparisons.

Figure 17: Uncertainty estimates for Pythia-70m metrics computed over five random seeds, showing the stability of the trained, randomized, and control comparisons.

F EFFECT OF SAE HYPERPARAMETERS FOR PYTHIA-160M

Figure 18: Hyperparameter robustness for Pythia-160m SAEs. Across expansion factors R from 16 to 128 and sparsities k of 16 and 32, the standard metrics preserve the relative ordering among trained, randomized, and control variants, supporting the default setting $R = 64$, $k = 32$.

G EFFECT OF SAE HYPERPARAMETERS FOR PYTHIA-1B

Figure 19: Hyperparameter comparison for Pythia-1b SAEs, including the default setting from Figure 2. A very small SAE ($R = 2, k = 4$) is clearly worse on explained variance and CE loss score, but its auto-interpretability scores remain close to those of default-hyperparameter SAEs trained on either trained or randomized models.

H TOKEN DISTRIBUTION ENTROPY VS. AUTO-INTERPRETABILITY

Figure 20: Per-latent comparison of token-distribution entropy and ‘fuzzing’ AUROC for SAEs trained on multiple Pythia-6.9b layers. Each point is one sampled latent from the same evaluation set used in Figures 1 and 2, so the plot shows which latents support the aggregate AUROC averages and whether high scores coincide with token-specific or more distributed activation patterns.

Figure 20 separates the variants along both axes, clarifying how similar aggregate AUROC values can arise from different latent populations:

- **Control:** Latents cluster at high entropy and low auto-interpretability: activation mass is spread across many tokens, and the generated explanations do not reliably predict those activation patterns. There is no evident correlation between the two variables.
- **Randomized:** Across the randomization schemes in Section 3, entropy is negatively correlated with auto-interpretability. Latents activated by a wider variety of token IDs are less well explained by their generated descriptions, while token-specific latents can score well.
- **Trained:** The correlation is weaker, and the trained model contains latents with both high entropy and high auto-interpretability. These points indicate activation patterns distributed over multiple tokens that nevertheless remain consistent with the generated explanation.

This two-dimensional view supports the main interpretation: aggregate auto-interpretability averages obscure differences between trained and randomized SAEs. Randomized models with stable token embeddings can produce explainable ‘single-token’ features, whereas transformers trained on natural language also produce higher-entropy semantic features that remain explainable.

I A TOY MODEL OF SUPERPOSITION

Section 4 compares SAE sparsity–reconstruction frontiers on explicitly superposed toy data (Sharkey et al., 2022), GloVe word vectors (Pennington et al., 2014), matched Gaussian controls, and random-MLP outputs. This appendix records the data-generation and training details underlying those quantitative comparisons.

I.1 DATA GENERATION

We construct the toy dataset by first sampling n_s ground-truth feature directions on an n_d -dimensional hypersphere.

For each sample, feature coefficients are generated by drawing $A \in \mathbb{R}^{n_s \times n_s}$ with $A_{ij} \sim \mathcal{N}(0, 1)$, setting $\Sigma = AA^\top$, sampling $\vec{\alpha} \in \mathbb{R}^{n_s}$ with $\alpha_i \sim \mathcal{N}(\vec{0}, \Sigma)$, projecting α_i through the c.d.f. of $\mathcal{N}(0, 1)$, applying the decay $\alpha_i \rightarrow \alpha_i^\lambda$ for $\lambda \in \mathbb{R}$, normalizing with $\alpha_i \rightarrow m\alpha_i / n_s \sum_j \alpha_j$ for $m \in \mathbb{R}$, and then performing n_s independent Bernoulli trials with $p = \alpha_i$. The nonzero coefficients are obtained by multiplying the trial outcomes by n_s independent draws from $\mathcal{U}_{[0,1]}$.

The decay parameter λ controls how quickly nonzero feature frequency falls with feature index i . The parameter m sets the expected number of nonzero feature coefficients per sample.

Following Sharkey et al. (2022), the experiments use $n_s = 512$, $n_d = 256$, $\lambda = 0.99$, and $m = 5$. Figure 21 gives a Python implementation of the same data-generation procedure.

I.2 TRAINING

The toy-model SAEs in Section 4 use a linear encoder with a bias term, a ReLU activation, and a linear decoder without a bias term. Decoder weights are initialized orthogonally, and decoder vectors are normalized before every training step so that sparsity comparisons are not driven by decoder scale.

The training objective is mean squared reconstruction error plus the mean L^1 norm of the encoded vectors, scaled by a coefficient swept from 1×10^{-3} to 100 to trace sparsity–reconstruction frontiers.

For the toy data, each SAE is trained for 100 epochs on 10K data points across 10 random seeds. For the word-vector experiments, each SAE is trained for 100 epochs on 400K data points with one random seed. In both cases, 10% of the data is held out as a validation set for the reported metrics.

The random MLPs in Section 4 have two layers, one hidden layer, and a ReLU activation. Both input and output size equal n_d , and the hidden size is $4n_d$. This dimension ratio is loosely chosen to resemble the feed-forward components of transformer language models.

Figure 21: Python implementation of the sparse toy-data generator from Sharkey et al. (2022), used for the frontier comparisons in Section 4.

Figure 22: Toy-data Pareto frontiers comparing explained variance with L^0 sparsity for superposed inputs, matched Gaussian controls, and the corresponding random-MLP outputs. The plot exposes sparsity margins at matched reconstruction quality.

Figure 23: Toy-data Pareto frontiers comparing explained variance with L^1 sparsity for superposed inputs, matched Gaussian controls, and the corresponding random-MLP outputs. Each curve shows how the sparsity–reconstruction tradeoff changes after the random network.

Figure 24: Toy-data Pareto frontiers comparing explained variance with $L^1/\sqrt{L^2}$ sparsity for superposed inputs, matched Gaussian controls, and the corresponding random-MLP outputs. The frontier gaps summarize the empirical sparsity advantage of each condition.

Figure 25: Toy-data Pareto frontiers comparing explained variance with Hoyer sparseness for superposed inputs, matched Gaussian controls, and the corresponding random-MLP outputs. This alternative sparsity metric checks that the qualitative frontier pattern is not metric-specific.

Figure 26: Pareto-frontier comparison for 50-dimensional GloVe word vectors, matched Gaussian controls, and their random-MLP outputs. The curves show the explained-variance versus sparsity margins for language-derived vectors.

Figure 27: Pareto-frontier comparison for 100-dimensional GloVe word embeddings, matched Gaussian controls, and their random-MLP outputs. The plot reports whether random-MLP propagation improves the sparsity–reconstruction tradeoff.

Figure 28: Pareto-frontier comparison for 200-dimensional GloVe word embeddings, matched Gaussian controls, and their random-MLP outputs. The curves make the input-control and output-control sparsity margins directly comparable.

Figure 29: Pareto-frontier comparison for 300-dimensional GloVe word embeddings, matched Gaussian controls, and their random-MLP outputs. This is the full-size GloVe setting used in the main toy-model discussion.

K COMPUTE DETAILS

We performed all experiments with a single NVIDIA A100 80GB GPU in a private cluster. Table 1 lists the approximate duration of the final experiments for each model size and transformer variant. We estimate that the total cost of preliminary and failed experiments is roughly equal to the cost of the final experiments.

Model	Variants	Approx. time per variant (hours)	Total time (hours)
Pythia-6.9b	5	70	350
Pythia-1b	5	10	50
Pythia-410m	5	5	25
Pythia-160m	5	1	5
Pythia-70m	5	1	5
Overall time:			435

Table 1: Approximate GPU time for the final experiment set, reported by model size and variant count.

L EXAMPLE FEATURE DASHBOARDS FOR PYTHIA-6.9B

Here we provide more detailed ‘feature dashboards,’ including per-feature activation patterns, token distribution entropy, and auto-interpretability (‘fuzz’ ROC) scores. We include two randomly sampled features for the control, randomized, and trained variants described in Section 3, trained on every fourth layer of Pythia-6.9b.

L.1 TRAINED

Feature 10065 (Layer 0) - Trained

Entropy: 0.009 | Fuzz ROC: 0.961

Interpretation: Prefixes or words starting with "Re" often indicating repetition, return, or renewal.

Ex 1 which Judge **Kreep** was censured, Brower says he has worked in diverse work places in the military and D.A.'s office, also working with
