

AUTOMATED INTERPRETABILITY METRICS DO NOT DISTINGUISH TRAINED AND RANDOM TRANSFORMERS

Anonymous submission

ABSTRACT

Sparse autoencoders (SAEs) are a general-purpose tool for extracting sparse, interpretable latents from transformer activations across language-model settings. We ask whether widely used SAE quality metrics and automatic explanation pipelines can separate representations produced by trained transformers from those produced by randomly initialized counterparts (e.g., with parameters sampled i.i.d. from a Gaussian). Across Pythia model sizes and several randomization schemes, we find that, in many of the evaluated conditions, SAEs trained on randomly initialized transformers attain auto-interpretability scores and reconstruction metrics close to those obtained from trained models. These results indicate that high aggregate auto-interpretability scores, considered in isolation, do not establish that an SAE has recovered learned, computationally relevant features. We therefore frame common SAE metrics as useful but incomplete proxies for mechanistic interpretability, and recommend routine randomized baselines together with targeted measures of feature ‘abstractness.’

1 INTRODUCTION

Sparse autoencoders (SAEs) are now a broadly used component of mechanistic interpretability workflows, where they are applied to neural activations in order to separate them into sparse, human-interpretable latents (Elhage et al., 2022; Sharkey et al., 2022; Cunningham et al., 2023; Bricken et al., 2023). In this setting, an autoencoder with an expanded hidden layer reconstructs activations under a sparsity constraint (Gao et al., 2024; Templeton et al., 2024; Lieberum et al., 2024), with the broader goal of identifying concepts or ‘features’ represented by the underlying network (Park et al., 2023; Wattenberg and Viégas, 2024). As SAEs are adopted across model families, layers, and downstream interpretability studies, their development increasingly depends on quantitative metrics, including auto-interpretability scores that compare generated explanations with observed activation patterns (Bills et al., 2023; Paulo et al., 2024; Karvonen et al., 2024a).

For an interpretability evaluation to support claims about learned mechanisms, it should help distinguish structure acquired through training from structure induced by the data distribution, architecture, or measurement procedure. A broadly applicable sanity check is therefore to compare outputs on trained models with outputs on strong null models, including models whose weights are randomly initialized (Adebayo et al., 2020). We apply this check to SAEs and find that several common quantitative metrics do not consistently separate trained transformers from randomized variants under our evaluated conditions. In particular, SAEs trained on transformers with random parameters can produce latents whose auto-interpretability scores (Bills et al., 2023; Paulo et al., 2024) are close to those obtained from the corresponding trained models.

This pattern broadens the question of what SAE quality metrics certify across applications. A high auto-interpretability score alone need not imply that an SAE has isolated complex computations learned from training. The same score may also reflect more general statistical structure in the input data (Dooms and Wilhelm, 2024) or architectural inductive biases that remain present before learning occurs. Indeed, a randomly initialized network can still implement a simple transformation, such as preserving or amplifying sparse input structure (Section 4). Under this interpretation, an SAE may be accurately describing a real but comparatively generic computation, rather than a task-specific learned mechanism.

Although some SAE features in trained models evidently reflect learned computation, aggregate metrics commonly used in SAE evaluation are often too coarse to determine whether a particular feature belongs to this more complex class. The implication extends beyond the specific Pythia models studied here: randomized models provide a practical control whenever an interpretability claim depends on attributing discovered structure to training. More generally, SAE evaluations should assess not only whether latents can be described, but also whether they encode features that are abstract, causally relevant, or specific to learned behavior.

To motivate why these similarities may arise across the evaluated settings, we consider two broad hypotheses: (1) the input data already exhibits superposition, and randomly initialized neural networks largely preserve this superposition; and (2) randomly initialized neural networks amplify or even introduce superposed structure in the input data (e.g., given dense input generated i.i.d. from a Gaussian). We use toy models in Section 4 to show that both hypotheses are plausible, while leaving the dominant mechanism in transformer activations to future work.

2 RELATED WORK

Sparse dictionary learning The idea now called ‘superposition’ in neural-network interpretability has close analogues in earlier work on visual data and computational neuroscience. Olshausen and Field (1996; 1997) showed that simple-cell receptive fields in the mammalian visual cortex can be explained through sparse coding: many sensory signals are represented by activating only a small subset of neurons at a time. Coding theory provides a general lens for this problem of recovering ‘underlying signals’ from neural network activations (Marshall and Kirchner, 2024).

Sparse dictionary learning (SDL) formalizes this recovery problem by approximating input vectors as linear combinations of a small number of learned basis vectors. The learned basis is typically overcomplete, with more dimensions than the input space. SDL methods include Independent Component Analysis (ICA), which seeks a linear representation whose components are maximally statistically independent (Bell and Sejnowski, 1995; Hyvärinen and Oja, 2000). SAEs instantiate the same broad idea with a simple neural-network architecture (Lee et al., 2006; Ng, 2011; Makhzani and Frey, 2014). In the common transformer setting, a single-hidden-layer autoencoder much wider than the activation vector is trained with an objective that imposes or encourages sparse hidden activations, so that the learned representation may expose sparse structure in the data. We refer to one hidden-layer neuron, or dimension, as a **latent**.

Mechanistic interpretability In contemporary mechanistic interpretability, ‘features’ or concepts in language models are often treated as low-dimensional subspaces of internal activations (Park et al., 2023; Wattenberg and Viégas, 2024; Engels et al., 2024). When sparse or ‘superposed’ structure of this kind is present, it should in principle support interventions or steering: modifying or replacing activations to express different concepts and thereby influence model behavior (Meng et al., 2022; Zhang and Nanda, 2023; Heimersheim and Nanda, 2024; Makelov, 2024; O’Brien et al., 2024).

SAEs are one widely used approach for discovering such features, usually by training an autoencoder to reconstruct activations from a single neural-network layer, such as the transformer residual stream (Sharkey et al., 2022; Cunningham et al., 2023; Bricken et al., 2023). Proposed SAE architectures vary along several dimensions, often including the activation function following the linear encoder (Makhzani and Frey, 2014; Gao et al., 2024; Rajamanoharan et al., 2024b; Lieberum et al., 2024). The framework has also been extended through alternative objectives (Braun et al., 2024; Farnik et al., 2025) and through models that operate over multiple layers simultaneously (Yun et al., 2021; Lawson et al., 2024; Lindsey et al., 2024).

Beyond reconstruction error and preservation of the underlying model’s performance, SAE evaluations have asked whether latents capture specific concepts (Gurnee et al., 2023; Gao et al., 2024), factual knowledge (Huang et al., 2024; Chaudhary and Geiger, 2024), or representations that can be used to ‘unlearn’ concepts (Karvonen et al., 2024b).

Automatic neuron description Because SAEs can learn tens or hundreds of thousands of latents, exhaustive manual description is usually impractical. One approach is to identify the tokens that maximally activate a dictionary element in a text dataset and manually inspect the resulting patterns (Yun et al., 2021). More commonly, researchers collect latent activation patterns over a text dataset

and prompt a large language model to generate descriptions (e.g. Bills et al., 2023; Foote et al., 2023). These manual-inspection and auto-description workflows have become standard across SAE studies (e.g. Cunningham et al., 2023; Bricken et al., 2023; Gao et al., 2024; Templeton et al., 2024; Lieberum et al., 2024).

Bills et al. (2023) generate explanations for language-model neuron activations over dataset examples, simulate activations from those explanations, and score the explanations by comparing simulated and observed activations. This family of methods is commonly described as auto-interpretability. Paulo et al. (2024) propose classification-based fidelity measures for automatic descriptions that are cheaper to compute than full activation simulation, together with an open-source implementation. Choi et al. (2024) use best-of- k sampling to generate multiple explanations from different subsets of maximally activating examples. They then fine-tune Llama-3.1-8B-Instruct on the top-scoring explanations to obtain lower-cost ‘explainer’ and ‘simulator’ models.

Polysemanticity Lecomte et al. (2024) note that neurons can become polysemantic incidentally. A polysemantic neuron, or basis dimension, represents multiple interpretable concepts within a layer (Elhage et al., 2022; Scherlis et al., 2023); individual neurons in randomly initialized networks may therefore also be polysemantic. Our focus is instead on *superposition* (Elhage et al., 2022; Chan, 2024), a layer-level representational phenomenon rather than a property of a single neuron. Superposition allows a layer to represent more sparse features than it has dense neurons, because only a small number of concepts are active at any given token position.

Training only the embeddings Zhong and Andreas (2024) show that transformers can acquire surprising algorithmic capabilities when training is restricted to the embeddings. Their results illustrate that the behavior of an otherwise randomly initialized transformer can be shaped substantially by a small trained parameter subset. Our experiments address a different question: in addition to studying SAEs, we randomize *all* parameters, including embeddings, in the ‘Step-0’ and ‘Re-randomized incl. embeddings’ variants. The ‘Re-randomized excl. embeddings’ variant retains pre-trained embeddings, but we do not train embeddings while holding random weights fixed; instead, we freeze the pre-trained embeddings and randomize the remaining weights (Section 3).

Random transformers for board games Karvonen et al. (2024c) found that SAEs extracted meaningful structure from chess games more effectively when applied to pre-trained transformers than to random-weight transformers. This comparison highlights an important domain boundary for our results: board-game data differs substantially from language data. Language plausibly contains sparse, concept-aligned events, such as rare words or contexts (e.g., ‘serendipitous’), whereas strategically useful board-game concepts need not appear sparsely in the same way. Thus, evidence from board games and evidence from language can support different expectations about how randomized models interact with sparse input structure.

Random one-layer transformers Bricken et al. (2023) found that auto-interpretability scores could discriminate between random and trained one-layer transformers. Our results are compatible with this narrower setting: randomized variants receive relatively low auto-interpretability scores for smaller Pythia models (e.g., Pythia-70m), while the gap narrows for larger models (e.g., Pythia-6.9b).

3 RESULTS

We trained per-layer SAEs on residual-stream activation vectors from Pythia transformer language models ranging from 70M to 7B parameters (Biderman et al., 2023). To separate effects of training, initialization, embeddings, and input-token consistency, we compared SAEs trained on the following transformer variants:

- **Trained:** The standard trained model.
- **Re-randomized incl. embeddings:** All model parameters, including embeddings, are re-initialized by sampling Gaussian noise whose mean and variance match the corresponding trained weight matrix.

Figure 1: ‘Fuzzing’ ROC curves by layer for Pythia-6.9b, with 100 latents sampled per SAE. The trained model (gray) and randomized variants (colored) occupy a similar range, whereas the control (black) remains near chance (dotted), illustrating that aggregate AUROC alone is not enough to attribute latents to learned computation. Figure 2 reports additional metrics and model sizes, and Appendix E shows multiple random seeds.

- **Re-randomized excl. embeddings:** The same re-randomization procedure is applied to non-embedding weights, while the embedding and unembedding matrices remain those of the trained model.
- **Step-0:** For Pythia, the available step0 revisions provide the original initialization weights before learning (Biderman et al., 2023).
- **Control:** The trained model is evaluated with input token embeddings replaced at inference time by i.i.d. standard Gaussian samples for each token occurrence, so a token ID no longer has a consistent embedding vector. We expect auto-interpretability for this variant to be near chance.

In the primary experimental setting, each SAE was trained on 100M tokens from RedPajama (Weber et al., 2024) with an activation buffer of 10M tokens; Appendix C reports a subset of experiments showing similar behavior after training on one billion tokens. For Pythia models below 410M parameters, we trained an SAE at every layer. For Pythia-1b, we trained SAEs at every second layer, and for Pythia-6.9b, we trained SAEs at every fourth layer.

Unless otherwise stated, we used k -sparse autoencoders (TopK SAEs; Makhzani and Frey 2014; Gao et al. 2024) with expansion factor $R = 64$ and sparsity $k = 32$. To check that the qualitative conclusions were not tied to this single SAE configuration, we also trained SAEs on Pythia-160m with expansion factors given by powers of 2 from 16 to 128, and with sparsities 16 and 32 (Figure 18). Training follows Belrose et al. (2025), and evaluation follows Caden et al. (2025) and Karvonen et al. (2024a).

Auto-interpretability Once a feature explanation is generated, it can be evaluated through classification tasks that ask whether the described concept is present in text inputs. These classifiers can then be scored with standard metrics such as the area under the receiver operating characteristic (ROC) curve (AUROC). Paulo et al. (2024) propose ‘fuzzing’ and ‘detection’ tasks for this purpose. In ‘fuzzing’ scoring, positive and negative token examples for a latent (with non-zero and zero activations, respectively) are marked with special delimiters, and a language model is prompted to identify which examples are correctly delimited given the explanation. In ‘detection’ scoring, the language model instead identifies which examples contain activating tokens for the feature. Bills

et al. (2023) originally proposed ‘simulation’ scoring, based on the correlation between predicted and observed activations, but this procedure is more expensive to compute.

Except where noted, we use ‘fuzzing’ scores as our auto-interpretability measure because they have been shown to correlate with simulation scoring (Paulo et al., 2024). Appendix B reports corresponding AUROC curves for ‘detection’ scoring. For each SAE, defined by underlying model, variant, and layer, we randomly sampled 100 features for auto-interpretability evaluation. Our implementation follows Paulo et al. (2024). We generate explanations and predictions with Meta-Llama-3.1-70B-Instruct-AWQ-INT4, which is larger than the 8B models used by Choi et al. (2024) and open-source, unlike Bills et al. 2023.

The resulting auto-interpretability scores are much closer between the trained and randomized models than between either of these groups and the control (Figures 1 and 2). This similarity in ROC behavior shows that, for SAE latent explanations in these settings, ‘fuzzing’ auto-interpretability by itself need not meaningfully distinguish trained transformers from randomized ones.

Evaluation We next evaluated standard SAE metrics together with auto-interpretability AUROC for Pythia models ranging from 70M to 6.9B parameters. Consistent with the preceding result, the randomly initialized and re-randomized variants (Figure 2; blue, green, orange lines) are generally closer to the trained model (gray) than to the control (black).

The control differs most clearly in reconstruction-related metrics: cosine similarity between original activations and SAE reconstructions, as well as explained variance, are often much lower for the control, and its reconstruction errors tend to increase with depth while the other variants decrease. One possible explanation is that a Gaussian is the maximum-entropy distribution with fixed mean and variance (Jaynes, 2003); in this sense, Gaussian vectors may be comparatively unstructured and therefore difficult for SAEs to reconstruct. As Gaussian-distributed activations pass through successive transformer layers, they may become less Gaussian and more effectively ‘sparse,’ making reconstruction easier (Section 4).

The re-randomized variants (blue and orange) are also closer to the trained model than the Step-0 initialization variant (green), especially in the L^1 norms for larger models. We speculate that this occurs because parameter norms can differ substantially between trained checkpoints and their initial states, whereas our re-randomization procedure explicitly preserves the trained model’s per-matrix scale. Layerwise parameter scale may matter for controlling the growth of activations through the residual stream (Liu et al., 2020). In the AUROC plots, all non-control variants show increasing AUROC with model size. One possible explanation is that larger SAEs contain more specific latents, while smaller SAEs require each latent to cover more of the input distribution, changing the difficulty of the classification tasks.

Row five of Figure 2 reports the cross-entropy (CE) loss score, or loss recovered, as a function of layer. This score is the loss increase caused by replacing original activations with SAE reconstructions, divided by the loss increase caused by replacing the activations with zeros (‘ablated’). For the trained variant, the SAE scores are similar to values reported elsewhere in the literature (e.g., Kissane et al., 2024; Rajamanoharan et al., 2024a; Mudide et al., 2024). The CE loss score is only interpretable for the trained variant: for randomized variants, the underlying model loss is very poor whether activations are original or reconstructed.

Latent explanation complexity Even when aggregate auto-interpretability and SAE quality metrics are similar, they can mask qualitative differences in what the latents represent. We expected SAEs trained on randomized variants to recover comparatively simple text-dependent features, while trained transformers could support more complex and abstract features (Templeton et al., 2024). To make this distinction concrete, Appendix J gives randomly sampled features and maximally activating dataset examples for each Pythia-6.9b variant, with more detailed dashboards in Appendix L.

Across SAE applications to language data, many latents appear to activate on only one token ID or a small set of token IDs (e.g., Lin and Bloom, 2024; Dooms and Wilhelm, 2024). This motivates a simple proxy for feature complexity: given maximally activating examples, we ask whether a latent’s activation mass is concentrated on one token ID or spread across many IDs. We quantify this spread using the entropy of the observed distribution of latent activations over tokens; higher entropy indicates that activations are distributed across more token IDs and are therefore less token-specific.

Figure 2: Sparse autoencoder metrics across Pythia models from 70M to 6.9B parameters. Across model scales, the trained and randomized variants follow broadly similar layerwise trends, while the control differs more strongly; larger models show more consistent behavior across layers despite the different initialization conditions.

Figure 3: Illustration of how a randomly initialized neural network transforms superposed input data. We draw 10K samples of $n_s = 3$ sparse input features from a Lomax distribution with shape $\alpha = 1$ and scale $\lambda = 1$, then project them to $n_d = 2$ dense input features using an i.i.d. standard normal matrix. We pass the dense vectors through a two-layer ReLU MLP with hidden size $4n_d$ and recover $n_s = 3$ sparse outputs using the inverse of the previously generated projection matrix.

The distribution is computed as total latent activation per token across the maximally activating examples used by the auto-interpretability pipeline. Appendix H shows the relationship between this entropy measure and ‘fuzzing’ AUROC for individual latents.

The last row of Figure 2 reports this token-activation entropy. The negative control has consistently high entropy, as expected: because each token occurrence receives a fresh i.i.d. Gaussian embedding, a token ID has no stable embedding vector (Section 3). For the trained variant, entropy increases with depth, meaning that later-layer maximally activating examples are less often dominated by a single token ID. This pattern matches the expectation that later trained layers support more abstract features that are less tied to token embeddings. By contrast, randomized variants tend to have lower entropy than both the trained and control variants, indicating that their latents often activate specifically on one or a few token IDs.

Together with the preceding metrics, this entropy analysis suggests that standard SAE quality and auto-interpretability scores omit an important dimension of scope: the ‘abstractness’ of the features being described. Token-distribution entropy is only a proxy for abstractness, but it shows that randomized variants can achieve similar auto-interpretability scores while still relying heavily on simple, token-specific features. Unlike the trained variant, these randomized features do not show the same increase in complexity across layer depth.

4 A TOY MODEL OF SUPERPOSITION IN RANDOM NETWORKS

Section 1 proposed two broad explanations for why randomized transformers can yield sparse, interpretable SAE latents: input data may already exhibit superposition that neural networks preserve, or random neural networks may amplify or introduce superposed structure. We examine both possibilities with toy models designed to isolate these mechanisms. The results provide evidence that each mechanism is plausible, but they do not determine which dominates in the randomized-transformer experiments reported above.

4.1 MATRIX MULTIPLICATIONS PRESERVE SUPERPOSITION

We first use a simplified model to show that multiplication by a weight matrix W preserves superposition. Suppose superposed input data x is generated by drawing n_s i.i.d. ‘sparse’ features z from a heavy-tailed Lomax distribution, $z \sim \text{Lomax}(\alpha, \lambda)$. The higher-dimensional sparse vector z is projected to a lower-dimensional dense vector x by a matrix D , with small-variance Gaussian noise Σ added so that $x \sim \mathcal{N}(x; Dz, \Sigma)$. Multiplying by any matrix W gives $x' = Wx$, which is *also* generated by the same superposition model but with transformed mappings and noise covariance, namely $x' \sim \mathcal{N}(z; WDz, W\Sigma W^T)$.

The same intuition may extend beyond linear maps to neural networks with nonlinearities. Figure 3 visualizes dense activations passed through a simple feed-forward network, where $n_s = 3$ sparse features are projected to $n_d = 2$ dense features and the MLP outputs still appear superposed. The

Figure 4: Mean max cosine similarity (MMCS) between features learned by a standard SAE (decoder weight vectors) and the data-generating features as the L^1 penalty coefficient varies, following Sharkey et al. (2022). The curve shows a ‘Goldilocks zone’ in which SAEs nearly recover the data-generating features when enough latents are available.

example also suggests possible amplification: compared with the inputs (Figures 3a and 3b), the outputs (Figures 3d and 3c) contain fewer points between the visible ‘arms.’

4.2 DO RANDOM NNs PRESERVE OR AMPLIFY SUPERPOSITION?

To test this suggestion more systematically, we generated toy data following Sharkey et al. (2022): ground-truth features are sampled on a hypersphere, and correlated feature coefficients are generated so that only a small number are active (Appendix I.1). We passed these inputs through a two-layer MLP at initialization and trained separate SAEs on the inputs and on the outputs. As a control, we used Gaussian inputs with the same mean and standard deviation as the superposed toy data. All toy-model SAEs use a standard L^1 sparsity penalty (Appendix I.2).

Following Sharkey et al. (2022), we first verified that SAEs recover the ground-truth features used to generate the toy inputs (Figure 4). We measured mean max cosine similarity (MMCS) by taking, for each data-generating feature, the maximum cosine similarity with any learned SAE decoder vector and then averaging over data-generating features. MMCS is available only for the MLP inputs, where the ground-truth features are known, so outputs require a more general diagnostic. We therefore use an SAE’s ability to obtain low reconstruction error at high sparsity as a proxy for the degree to which the data exhibits superposition. Concretely, we vary the L^1 penalty coefficient to trace Pareto frontiers of explained variance against sparsity measures (Figure 5a).

As expected, SAEs achieve substantially higher sparsity at fixed explained variance for superposed inputs than for the Gaussian control (Figure 5a; orange and blue-green). After the inputs pass through the randomly initialized MLP, however, the gap between superposed-output and Gaussian-output frontiers becomes much smaller, with only slightly higher sparsity for the superposed outputs at a given explained variance. This suggests that randomly initialized MLP outputs can have a relatively high degree of sparsity that is less sensitive to the input distribution. Appendix I reports additional sparsity measures and hyperparameter settings.

4.3 DO TOKEN EMBEDDINGS EXHIBIT SUPERPOSITION?

If randomly initialized neural networks preserve or amplify superposition, then the transformer results in Section 3 may depend partly on whether language-model inputs already exhibit superposed structure. We study this possibility by applying the procedure from Section 4.2 to language-derived inputs. Specifically, we train SAEs on pre-trained GloVe word vectors, Pythia embedding matrices, the outputs obtained by passing these inputs through a randomly initialized two-layer MLP, and matched Gaussian controls. The setup matches Section 4.2, except that the number of data points is fixed by the number of word embeddings or tokens and we use a single random seed.

The Pareto-frontier gap between GloVe vectors and their Gaussian controls (Figure 5b) is smaller than the corresponding gap for the toy superposed datasets in Section 4.2 (Figure 5a). However, passing both inputs through a randomly initialized two-layer MLP again improves their Pareto frontiers,

(a) Toy datasets following Sharkey et al. (2022). (b) 300-dim. GloVe vectors (Pennington et al., 2014).

Figure 5: Pareto frontiers of explained variance against the L^1 norm divided by the square root of the L^2 norm (sparsity) for datasets that may exhibit superposition, Gaussian controls with the same mean and variance, and corresponding outputs after passing each dataset through a randomly initialized two-layer MLP (Section 4.2). Each point denotes one L^1 penalty coefficient.

supporting the broader possibility that random neural networks can ‘sparsify’ inputs by increasing apparent superposition.

5 LIMITATIONS

This study shows that auto-interpretability measures can assign apparently meaningful interpretations to SAEs trained on randomly initialized models, even though such models are unlikely to contain the kinds of learned computations often targeted by mechanistic interpretability. The evidence is necessarily scoped: we focus on the Pythia model family, which is widely used in mechanistic interpretability research (e.g., Paulo and Belrose, 2025; Ghilardi et al., 2025; Mueller, 2024), and on RedPajama-V2 data, a representative pre-training-style dataset for language models and SAEs, rather than attempting exhaustive coverage of all datasets and architectures.

We also use the default explanation model from the EleutherAI auto-interpretability framework (Caden et al., 2025); evaluating other explainer or simulator models could clarify which aggregate behaviors are specific to that pipeline and which are more general. Our claim is therefore not that SAEs fail to capture additional information from trained Transformers relative to randomized ones, but that aggregate auto-interpretability measures alone do not establish that the captured features are learned, computationally interesting, or specific to the trained model.

6 CONCLUSION

We applied sparse autoencoders to trained and randomly initialized transformers and evaluated them with common quantitative SAE metrics. Across the evaluated Pythia settings, our central finding is that these metrics, especially aggregate auto-interpretability scores, can be similar for trained and randomized variants. At the same time, qualitative examples and token-distribution entropy indicate that trained-transformer features can become more complex and abstract, especially in later layers, even when aggregate metrics do not reflect this difference.

This result should not be read as evidence that SAEs trained on real models lack meaningful computational features. Instead, it identifies a broader limitation of current evaluation practice. High aggregate auto-interpretability scores are not sufficient evidence for the discovery of complex learned

486 computations, because they may also reflect structure in the data or architecture that persists under
487 random weights. Our token-distribution entropy analysis is preliminary, but it provides a proof of
488 concept for measuring feature ‘abstractness’ in a way that exposes distinctions missed by aggregate
489 auto-interpretability. Future SAE evaluation should therefore quantify not only describability and
490 reconstruction quality, but also the computational significance and learned specificity of discovered
491 features. More broadly, interpretability techniques should be benchmarked against strong, appropri-
492 ately constructed null models, such as the randomly initialized transformers used here, whenever the
493 goal is to attribute a feature to learning rather than to generic structure.

A BROADER IMPACT

This work studies sparse autoencoders as a method used in mechanistic interpretability of LLMs, and it qualifies how broadly aggregate SAE evaluation scores should be interpreted. By showing that random and trained transformers can receive similar aggregate auto-interpretability scores under our evaluated conditions, the results raise a general methodological question about what these evaluation pipelines measure.

A clearer understanding of SAE quality metrics can support the development of more reliable SAE-like methods, improving interpretability tools that may help mitigate harms from deployed models. Because this paper is an empirical evaluation of an existing method, and because it emphasizes limitations and controls rather than adding new model capabilities, we expect the direct risk of negative social impact to be minimal.

B AUTO-INTERPRETABILITY ROC CURVES

Figures 6, 8, and 12 show that ‘fuzzing’ AUROC follows similar patterns for trained and randomized SAEs in the 70M, 160M, and 1B Pythia settings. Figures 7, 9, and 13 show the corresponding comparison for ‘detection’ AUROC, extending the same qualitative point to a second auto-interpretability task.

B.1 PYTHIA 70M

Figure 6: ROC curves for ‘fuzzing’ auto-interpretability on Pythia-70m over 100 SAE latents. The variants show similar layerwise behavior, including an overall degradation as layer index increases.

Figure 7: ROC curves for ‘detection’ auto-interpretability on Pythia-70m over 100 SAE latents. The variants show similar layerwise behavior, including an overall degradation as layer index increases.

B.2 PYTHIA 160M

Figure 8: ROC curves for ‘fuzzing’ auto-interpretability on Pythia-160m over 100 SAE latents. The variants show similar layerwise behavior, including an overall degradation as layer index increases.

Figure 9: ROC curves for ‘detection’ auto-interpretability on Pythia-160m over 100 SAE latents. The variants show similar layerwise behavior, including an overall degradation as layer index increases.

B.3 PYTHIA 410M

Figure 10: ROC curves for ‘fuzzing’ auto-interpretability on Pythia-410m over 100 SAE latents. The variants show similar layerwise behavior, including an overall degradation as layer index increases, and these aggregate scores do not separate trained and randomized models.

Figure 11: ROC curves for ‘detection’ auto-interpretability on Pythia-410m over 100 SAE latents. The variants show similar layerwise behavior, including an overall degradation as layer index increases.

B.4 PYTHIA-1B

Figure 12: ROC curves for ‘fuzzing’ auto-interpretability on Pythia-1b over 100 SAE latents. The variants show similar performance, but unlike the smaller settings, there is no overall degradation in quality.

Figure 13: ROC curves for ‘detection’ auto-interpretability on Pythia-1b over 100 SAE latents. The variants show similar performance, but unlike the smaller settings, there is no overall degradation in quality.

B.5 PYTHIA 6.9B

Figure 14: ROC curves for ‘detection’ auto-interpretability on Pythia-6.9b over 100 SAE latents. The trained and randomized variants again occupy a similar performance range.

C EFFECT OF INCREASED TRAINING DATA

The primary experiments use SAEs trained on 100M tokens (Section 3). To check whether the observed similarity between trained and randomized variants was an artifact of limited SAE training data, we repeated a subset of experiments with SAEs trained on 1B RedPajama tokens (Figure 15).

Figure 15: Evaluation metrics for SAEs trained on one billion tokens for Pythia-70m and Pythia-410m. These panels correspond to the same model columns in Figure 2, which uses 100M-token SAE training, and show qualitatively similar behavior.

D EFFECT OF DECREASED TRAINING DATA FOR PYTHIA-1B

Figure 16: Evaluation metrics for SAEs trained with 1M and 1B tokens on Pythia-1b. The 1M-token SAEs have substantially lower explained variance and CE loss score, indicating under-training. Average auto-interpretability scores are slightly lower in the earliest layers and decline sharply with depth, while layerwise trends in auto-interpretability and token-distribution entropy remain consistent with the other SAE settings.

1134 E UNCERTAINTY PLOTS FOR PYTHIA-70M

1135
1136 To assess seed-level variability in the smallest Pythia setting, we computed evaluation-metric uncer-
1137 tainty for Pythia-70m using five random seeds.

1187

Figure 17: Uncertainty estimates for Pythia-70m metrics computed across five random seeds.

F EFFECT OF SAE HYPERPARAMETERS FOR PYTHIA-160M

Figure 18: Robustness of SAE performance to hyperparameter selection. Standard evaluation metrics remain stable across expansion factors R from 16 to 128 and sparsities k from 16 to 32, with initialization strategies preserving their relative ordering. This stability supports using moderate hyperparameter values such as expansion factor $R = 64$ and sparsity $k = 32$ in the main experiments.

G EFFECT OF SAE HYPERPARAMETERS FOR PYTHIA-1B

Figure 19: Evaluation metrics for SAEs trained on Pythia-1b with different hyperparameters, including the main setting from Figure 2. SAEs with a very small expansion factor $R = 2$ and sparsity $k = 4$ are clearly separated from the default setting by explained variance and CE loss score, while their auto-interpretability scores remain similar to default-hyperparameter SAEs on both trained and randomised models.

H TOKEN DISTRIBUTION ENTROPY VS. AUTO-INTERPRETABILITY

Figure 20: Per-latent token-distribution entropy plotted against ‘fuzzing’ AUROC (auto-interpretability score) for SAEs trained on multiple Pythia-6.9b layers. Each point is a single latent from the same sample used to compute the aggregate metrics in Figures 1 and 2.

Figure 20 separates the negative control, randomized variants, and trained variant along a dimension that aggregate AUROC obscures:

- **Control:** Latents have consistently high entropy, meaning that maximally activating examples spread activation across many tokens, and low auto-interpretability scores, meaning that generated explanations do not adequately predict those activation patterns. No clear correlation between the two variables is visible.
- **Randomized:** For each randomization scheme in Section 3, entropy and auto-interpretability are negatively correlated: as a latent activates across a wider variety of tokens, its generated explanation generally explains the activation pattern less well.
- **Trained:** The correlation is weaker. In addition to the broad trend seen for randomized variants, trained models contain latents with both high entropy *and* high auto-interpretability, suggesting activation patterns spread across multiple tokens while remaining consistent with the generated explanation.

These results support the view that aggregate auto-interpretability scores can obscure differences between SAEs trained on trained and randomized models. Randomized models with consistent token embeddings can produce easily explained ‘single-token’ features, whereas transformers trained on natural language are the only variants here that produce the more complex semantic features indicated by high entropy and high auto-interpretability.

I A TOY MODEL OF SUPERPOSITION

Section 4 uses SAEs trained on toy data designed to exhibit superposition (Sharkey et al., 2022) and on GloVe word vectors (Pennington et al., 2014). This appendix specifies the data-generation procedure and training setup for those analyses.

I.1 DATA GENERATION

We construct the ground-truth feature basis by sampling n_s points on an n_d -dimensional hypersphere.

For each sample, feature coefficients are generated by drawing $A \in \mathbb{R}^{n_s \times n_s}$ with $A_{ij} \sim \mathcal{N}(0, 1)$, defining $\Sigma = AA^T$, sampling $\vec{\alpha} \in \mathbb{R}^{n_s}$ with $\alpha_i \sim \mathcal{N}(\vec{0}, \Sigma)$, projecting α_i through the c.d.f. of $\mathcal{N}(0, 1)$, applying the decay $\alpha_i \rightarrow \alpha_i^{\lambda_i}$ for $\lambda \in \mathbb{R}$, normalizing with $\alpha_i \rightarrow m\alpha_i / n_s \sum_j \alpha_j$ for $m \in \mathbb{R}$, and performing n_s independent Bernoulli trials with $p = \alpha_i$. The resulting trial outcomes are then multiplied by n_s independent samples from the continuous uniform distribution $\mathcal{U}_{[0,1]}$.

The parameter λ controls how sharply the frequency of nonzero ground-truth feature coefficients decays with feature index i . The parameter m sets the expected number of nonzero feature coefficients in each sample.

Following Sharkey et al. (2022), we set $n_s = 512$, $n_d = 256$, $\lambda = 0.99$, and $m = 5$. Figure 21 provides a Python implementation of the procedure.

I.2 TRAINING

The SAEs used in Section 4 consist of a linear encoder with a bias term, a ReLU activation, and a linear decoder without a bias term. Decoder weights are initialized orthogonally and decoder weight vectors are normalized before each training step.

The training objective is mean squared error (MSE) between input and decoded vectors plus the mean L^1 norm of the encoded vectors multiplied by a coefficient varied between 1×10^{-3} and 100.

For toy data, we train for 100 epochs on 10K data points using 10 random seeds. For word vectors, we train for 100 epochs on 400K data points using one random seed. In both cases, 10% of data points are held out as a validation set for computing evaluation metrics.

The MLPs in Section 4 have two layers, one hidden layer, and a ReLU activation. Their input and output sizes are both n_d , with hidden size $4n_d$. These choices loosely mirror the feed-forward components of transformer language models while remaining simple enough for controlled toy experiments.

K COMPUTE DETAILS

All experiments were run on a single NVIDIA A100 80GB GPU in a private cluster. Table 1 reports the approximate duration of the final experimental runs for each model size and transformer variant. We estimate that preliminary and failed runs required roughly the same total compute as the final experiments.

Model	Variants	Approx. time per variant (hours)	Total time (hours)
Pythia-6.9b	5	70	350
Pythia-1b	5	10	50
Pythia-410m	5	5	25
Pythia-160m	5	1	5
Pythia-70m	5	1	5
Overall time:			435

Table 1: Approximate GPU time required for the final experiments.

L EXAMPLE FEATURE DASHBOARDS FOR PYTHIA-6.9B

This appendix provides more detailed feature dashboards, including per-feature activation patterns, token-distribution entropy, and auto-interpretability (‘fuzz’ ROC) scores. The dashboards cover two randomly sampled features for the control, randomized, and trained variants from Section 3, using SAEs trained on every fourth layer of Pythia-6.9b.

L.1 TRAINED

Feature 10065 (Layer 0) - Trained

Entropy: 0.009 | Fuzz ROC: 0.961

Interpretation: Prefixes or words starting with "Re" often indicating repetition, return, or renewal.
